Aerobic cytotoxicity of 3-amino-1,2,4-benzotriazine-1,4-dioxide (tirapazamine, TPZ), a bioreductively activated hypoxia-specific anticancer agent, is responsible for TPZ side effects in chemotherapy. In order to clarify its mechanisms, we examined the aerobic cytotoxicity of TPZ and its main metabolites, 3-amino-1,2,4-benzotriazine-1-oxide and 3-amino-1,2,4-benzotriazine in murine hepatoma MH22a cells, and their reduction by NADPH:cytochrome P-450 reductase (P-450R) and ferredoxin:NADP⁺ reductase (FNR). Analogous studies of several quinones and nitroaromatic compounds with similar values of single-electron reduction midpoint potentials ($E_{1/2}$) were carried out. In single-electron reduction by P-450R and FNR, the reactivity of TPZ and its monoxide was similar to that of quinones and nitroaromatics, and increased with an increase in their $E_{1/2}$. The cytotoxicity of TPZ and its metabolites possessed a prooxidant character, because it was partly prevented by an antioxidant $N,N'$-diphenyl-p-phenylene diamine and desferrioxamine, and potentiated by 1,3-bis(2-chloroethyl)-1-nitrosourea. Importantly, the cytotoxicity of TPZ and, possibly, its 1-N-oxide, was much higher than that of quinones and nitroaromatics with similar values of $E_{1/2}$ and redox cycling activities. A possible additional factor in the aerobic cytotoxicity of TPZ is its reductive activation in oxygen-poor cell nuclei, leading to the formation of DNA-damaging species similar to those forming under hypoxia.

Keywords: tirapazamine, cytotoxicity, oxidative stress, reductive activation

Abbreviations: $E_{1/2}$, single-electron reduction midpoint potential; FNR, ferredoxin:NADP⁺ reductase; $k_{cat}$, turnover number; $k_{cat}/K_m$, apparent bimolecular rate constant; NQO1, DT-diaphorase; P-450R, NADPH:cytochrome P-450 reductase; SOD, superoxide dismutase; TPZ, tirapazamine

INTRODUCTION

3-Amino-1,2,4-benzotriazine-1,4-dioxide (tirapazamine, TPZ) and its analogs are hypoxia-selective anticancer agents ([1], and references therein). TPZ (1) is enzymatically reduced in a single-electron way to a free radical (2), which forms DNA-damaging species under hypoxic conditions, namely, an oxidizing hydroxyl radical (OH·) ([2], and references therein), and/or a highly reactive

* Corresponding author. Email: narimantas.cenas@bchi.vu.lt
benzotriazinyl radical (3) that abstracts a hydrogen atom from DNA (5, 6, and references therein) (Fig. 1). The nature of DNA-damaging species is still a matter of debate. In the cell, TPZ is converted into two main relatively non-toxic metabolites, its mono-1-oxide (4), possibly via free radical (2) intermediate (7), and its nor-oxide (6), presumably via 4-oxide (5) intermediate (Fig. 1) (8).

The single-electron reductive activation of TPZ under hypoxic andoxic conditions is carried out mainly by microsomal NADPH:cytochrome P-450 reductase (P-450R) (9, and references therein), and/or by insufficiently characterized intranuclear NAD(P)H-oxidizing flavoenzymes (10). DT-diaphorase (NQO1) also reduces TPZ into 4 and 6, however, its role in TPZ cytotoxicity is minor (8, 9).

Because the aerobic cytotoxicity of aromatic di-N-oxides is lower than under hypoxia, it attracted considerably less attention (10, 11). In the simplest way, it is explained by the redox cycling of TPZ (Fig. 1), leading to the formation of superoxide (O$_2^-$) and subsequent oxidative stress (11). This is considered as the side effect in tumour therapy (11, 12, and references therein). However, some TPZ analogues possess anticancer activity at micromolar concentrations even under oxic conditions (13, 14). Besides, redox cycling events play an important role in the antimicrobial and anti-parasitic action of TPZ analogs (15, and references therein). For these reasons, the aerobic cytotoxicity of TPZ deserves more thorough studies.

In this work, we examined the aerobic cytotoxicity and enzymatic redox properties of TPZ and its metabolites 4 and 6. We found that the cytotoxicity of TPZ is considerably higher than that of model quinones and nitroaromatic compounds with similar values of single-electron reduction midpoint potentials ($E^*$) and redox cycling activities.

**MATERIALS AND METHODS**

TPZ, 3-amino-1,2,4-benzotriazine-1-oxide and 3-amino-1,2,4-benzotriazine were synthesized as described in (10, 16, and 17), respectively. The compound purity was characterized by IR and NMR spectrometry, the melting point, and elemental analysis. NADPH, cytochrome c, superoxide dismutase, and other reagents were obtained from Sigma, and used as received. Recombinant rat NADPH:cytochrome P-450 reductase (P-450R) was prepared as described in (18), and was a generous gift of Dr. Alexey Yantsevich (Institute of Bioorganic Chemistry, Minsk, Belarus). The enzyme concentration was determined spectrophotometrically according to $e_{456} = 21.4$ mM$^{-1}$ cm$^{-1}$.

![Fig. 1. A scheme of the reduction of tirapazamine in the cell](image)
Recombinant *Plasmodium falciparum* ferredoxin:NADP⁺ reductase (FNR) was prepared as described in [13], and was a generous gift of Dr. Alessandro Aliverti (Università degli Studi di Milano, Italy). The enzyme concentration was determined according to ε_{465} = 10.1 mM⁻¹ cm⁻¹.

The kinetic measurements were carried out spectrophotometrically using a Cary 60 UV–VIS spectrophotometer (Agilent Technologies) in the 0.1 M K-phosphate buffer (pH 7.0) containing 1 mM EDTA at 25°C. Enzymatic NADPH oxidation rates were determined according to Δε_{340} = 6.2 mM⁻¹ cm⁻¹ after the subtraction of intrinsic NADPH oxidase activities of enzymes, 0.05 s⁻¹ (P-450R) and 0.07 s⁻¹ (FNR). The values of the turnover rate, k₅₅₀, reflecting the maximal number of moles NADPH oxidized or oxidant reduced per mole of the enzyme active center per second, and k₅₅₀/Kₘ, the apparent bimolecular rate constant, correspond to the inverse intercepts and slopes in Lineweaver–Burk coordinates, [E]/[oxidant] vs 1/[oxidant]. These rate constants were obtained by fitting the experimental data to the Michaelis–Menten equation using the Sigmaplot software. The rates of reduction of cytochrome c and ferricyanide were monitored according to Δε_{550} = 20 nM⁻¹ cm⁻¹ and Δε_{420} = 1.0 mM⁻¹ cm⁻¹, respectively. At the saturating concentration of substrates, 100 µM NADPH and 50 µM cytochrome c or 1.0 mM ferricyanide, the k₅₅₀ of P-450R was equal to 39 s⁻¹ (cytochrome c), and the k₅₅₀ of FNR was equal to 50 s⁻¹ (ferricyanide). The k₅₅₀ of NQO1 was monitored according to the rate of menadione-mediated reduction of cytochrome c.

Murine hepatoma MH22a cells were grown and maintained at 37°C in the DMEM medium, supplemented with 10% fetal bovine serum and antibiotics, as described in [24]. In the cytotoxicity experiments, 3.0 × 10⁴/ml cells were seeded on 18x18 mm glass slides in 5-ml flasks either in the presence or in the absence of compounds, and were grown for 24 h. Then, the slides were rinsed 3–4 times with phosphate buffered saline and stained with Trypan blue. The cells adherent to the slides were counted under a light microscope. Typically, they did not accumulate Trypan blue and their viability was 98.5–99.3%. Stock solutions of compounds were prepared in dimethyl sulfoxide. Its concentration in cultivation media did not exceed 0.2%, and did not affect the cell viability. The experiments were conducted in triplicate.

The statistical analysis was performed using Statistica (version 4.3, StatSoft, 1993) and octanol/water partition coefficients (log P<sub>oct</sub>) were calculated using a Log P calculator (version 2015, ACD Labs).

**RESULTS**

Frequently, the aerobic cytotoxicity of quinones and nitroaromatic compounds increases with an increase in their single-electron reduction midpoint potential at pH 7.0 (E<sub>c</sub>) with the relationship Δlog cL<sub>50</sub>/ΔE<sub>c</sub> ≈ −10 V⁻¹, where cL<sub>50</sub> is the concentration of the compound for 50% cell survival ([21], [22], and references therein). It points to the oxidative stress being the main factor of cytotoxicity, because, as a rule, the rates of single-electron reduction of quinones or nitroaromatics by flavoenzymes initiating redox cycling increase with E<sub>c</sub> of an oxidant ([23]–[25]). To examine the relationship of TPZ cytotoxicity with its redox cycling activity, we determined the steady-state reduction rate constants of TPZ and its metabolites by NADPH:cytochrome P-450 reductase (P450R) which is supposed to be one of the major determinants of TPZ cytotoxicity [6], and by a model single-electron transferring enzyme, ferredoxin:NADP⁺ reductase (FNR) [24]. In parallel, the reduction rate constants of a number of quinones and nitrobenzenes with low E<sub>c</sub> values, −0.260 V – −0.485 V, were determined (Table 1).

In the FNR-catalyzed reactions, the rates of reduction of added cytochrome c (50 µM) were equal to 180–190% of the NADPH oxidation rate in the presence of TPZ, its 1-oxide and nor-oxide. The reaction was inhibited by 100 U/ml superoxide dismutase by 40–50%. It shows that cytochrome c is reduced by free radicals of these compounds undertaking the redox equilibrium with a O₂/O⁻<sub>2</sub> couple. The data of Fig. 2 show that the reactivity (log k₅₅₀/Kₘ) of TPZ and its 1-oxide in P-450R-catalyzed reduction is in the range of reactivities of quinones and nitroaromatic compounds with similar values of E<sub>c</sub>. In general, the log k₅₅₀/Kₘ of compounds increases with an increase in their E<sub>c</sub>, although a linear regression between these two parameters is scattered (r² = 0.7985). A similar although more scattered relationship is characteristic of FNR reactions (data not shown). Interestingly, 3-amino-1,2,4-benztiazine reacted with P-450R and FNR with rates similar to TPZ and its 1-N-oxide (Table 1). The E<sub>c</sub> value of...

$^a$From [3, 26].

In this cell line, log $cL_{50}$ of quinones exhibit a negative linear dependence on their $E_1^\gamma$ values in the range of −0.15 V – −0.41 V [29]. We found that the log $cL_{50}$ of the examined nitroaromatic compounds also followed this rule, however, the cytotoxicity of TPZ and its 1-N-oxide metabolite was higher than expected (Table 2, Fig. 3A).

Alternatively, for the data analysis involving 3-amino-1,2,4-benzotriazine with an unavailable value of $E_1^\gamma$, we applied the previously used approach for description of the prooxidant cytotoxicity of nitroaromatics and quinones, namely the geometrical mean of their reactivity in P-450R and FNR-catalyzed reactions (0.5 log $k_{cat}/K_m$ (P-450R) + 0.5 log $k_{cat}/K_m$ (FNR)) [28, 29] (Table 2). In this case, a significant deviation from a linear regression is evident only for TPZ (Fig. 3B).

Enhanced cytotoxicity of TPZ and, possibly, its 1-oxide may not be attributed to their higher lipophilicity, because their calculated log $P$ values are even lower than those of other examined compounds (Table 2).

The data of Fig. 4 show that the cytotoxicity of TPZ and its nor-oxide derivative was decreased in the presence of antioxidant $N,N'$-diphenyl-$p$-phenylene diamine (DPPD) and Fe-ion chelator desferoxamine, and enhanced by 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU), the latter inactivating glutathione reductase and depleting reduced glutathione [30]. Analogous effects were observed studying the cytotoxicity of 1-oxide of TPZ and other compounds (data not shown).

*From [20].

Fig. 3. The dependence of cytotoxicity of the examined compounds in MH22a cells on their single-electron reduction midpoint potential ($E_{1/2}^\Gamma$) (A), and on the geometrical mean of their reactivity in P-450R and FNR-catalyzed reactions (0.5 log $k_{\text{cat}}/K_m$(P-450R) + 0.5 log $k_{\text{cat}}/K_m$(FNR)) (B). The numbers of compounds are taken from Tables 1 and 2. The first order regression lines were drawn through the values of cL_{50} of compounds 4–10 (A) and 2–10 (B).
An inhibitor of NQO1, dicumarol (20 μM), protected against the TPZ cytotoxicity, however, its effects were statistically insignificant.

DISCUSSION

Our data show for the first time that the reactivity of TPZ and its 1-oxide towards single-electron transferring flavoenzymes P-450R and FNR is comparable to that of quinones and nitroaromatics, and varies according to their $E_{1/2}$ (Table 1, Fig. 2). This provides a background for the quantitative interpretation of TPZ cytotoxicity.

The modulation of cytotoxicity of TPZ and its metabolites by antioxidants and prooxidant BCNU (Fig. 4) is in line with the suggested oxidative stress-type aerobic cytotoxicity of TPZ [1]. The lower cytotoxicity of TPZ metabolites as compared with the parent compound (Table 2) is in line with the previous findings ([11], and references therein). However, the data of Fig. 3A, B show that the cytotoxicity of TPZ and, possibly, its 1-oxide is much higher than may be expected from their $E_{1/2}$ value and redox cycling ability. Concerning the possible additional factors of TPZ cytotoxicity, let us first address the role of NQO1, which, according to the earlier studies, was modest or even absent [8, 9]. In our case the protecting effects of the inhibitor of NQO1, 20 μM dicumarol were also statistically insignificant. Thus, the action of NQO1 may not be the factor determining an enhanced cytotoxicity of TPZ over the ‘model’ redox cycling compounds. An attractive alternative possibility is that a high aerobic cytotoxicity of TPZ stems from the specific redox chemistry of aromatic N-oxides, namely, the formation of oxidizing and DNA-damaging species from their radicals (Fig. 4), which is not characteristic of quinones and nitroaromatics. Although these events take place under hypoxia, they may manifest themselves in relatively poorly oxygenated cell compartments, e.g. nucleus [31], but with a lower efficiency. This assumption is in line with the data of [7], which point to the leading role of the intranuclear reductive activation of TPZ in its hypoxic cytotoxicity. Our studies on further differences between the mechanisms of the aerobic cytotoxicity of aromatic di-N-oxides, quinones and nitroaromatic compounds including the apoptosis induction are currently underway.

CONCLUSIONS

Our data show that the aerobic cytotoxicity of TPZ and, possibly, its 1-oxide in MH22a hepatoma cells is much higher than may be expected from their $E_{1/2}$ value and redox cycling ability. It possibly stems from the specific redox chemistry of aromatic N-oxides, namely, the formation of oxidizing and DNA-damaging species from their radicals, which is not characteristic of quinones and nitroaromatics. Although these events take place under hypoxia, they may manifest themselves in relatively poorly oxygenated cell compartments, e.g. nucleus, but with a lower efficiency.

TIRAPAZAMINO IR JO 1-OKSIDO BEI NOR-OKSIDO METABOLITŲ VIENELEKTRONINĖ FERMENTINĖ REDUKCIJA IR JŲ AEROBINIS CITOTOKSIŠKUMAS

Santrauka
Bioredukciškai aktyvuojamo hipoksijai selektyvaus priešnavikinio agento 3-amino-1,2,4-benzotriažino-1,4-diokside (tirapazamino, TPZ) aerobinis citotoksiškumas sukélia pašalinius efektus chemoterapijoje. Siekdami išaiškinti jų mechanizmus, ištyrėme aerobinį TPZ ir jo pagrindinių metabolitų 3-amino-1,2,4-benzotriažino-1-oksido ir 3-amino-1,2,4-benzotriažino citotoksiškumą pelės hepatomos MH22a ląstelėse ir jų redukciją NADPH: cytochromo P-450 reduktaze (P-450R) ir ferredoksin:NADP⁺ reduktaze (FNR). Analogiškai buvo ištirti keli chinonai ir nitroaromatiniai junginiai, turintys panašius vienelektroninės redukcijos potencialus (\(E^1\)). Vienelektroninis redukcijos P-450R ir FNR atveju TPZ ir jo monoksido reakcingumas buvo artimas chinonų ir nitroaromatinių junginių reakcingumui ir didėjo didėjant jų \(E^1\). TPZ ir jo metabolitų citotoksiškumas buvo prooksidantinis, nes jis buvo slopenamas antioksidantų N,N'-difenil-p-fenilen diamino ir desferioksamino bei stiprinamas 1,3-bis(2-chloretil)-1-nitrozokarbamido. Svarbu tai, kad TPZ ir, galimai, jo 1-oksido citotoksiškumas buvo daug didesnis nei panašus \(E^1\), ar ciklinių redoks viršų aktyvumo chinonų arba nitroaromatinių junginių. Galimai papildomas TPZ aerobinio citotoksiškumo veiksny ir jis reducinė aktyvacija ląstelės branduolyje, kur dėl žemesnės deguonies koncentracijos susidarо DNR pažeidžiantys produktai, analogiški susidarantiesių hipoksiškos sąlygomis.
